

Search for Single Top Quark Production at HERA

H1 Collaboration

Abstract

A search for single top quark production is performed in the full $e^{\pm}p$ data sample collected by the H1 experiment at HERA, corresponding to an integrated luminosity of 474 pb^{-1} . Decays of top quarks into a b quark and a W boson with subsequent leptonic or hadronic decay of the W are investigated. A multivariate analysis is performed to discriminate top quark production from Standard Model background processes. An upper limit on the top quark production cross section via flavour changing neutral current processes $\sigma(ep \rightarrow etX) < 0.25 \text{ pb}$ is established at 95% CL. Limits on the anomalous coupling $\kappa_{tW\gamma}$ are derived.

1 Introduction

Top quarks are of particular interest in searches for new physics because their mass is close to the electroweak scale. In $e^\pm p$ collisions at HERA the production of single top quarks is kinematically possible due to the large centre of mass energy of up to $\sqrt{s} = 319$ GeV. Within the Standard Model (SM) the production of top quarks at HERA is however strongly suppressed. Therefore the observation of single top quark production would be a clear indication of new physics. In several extensions of the SM the top quark is predicted to undergo flavour changing neutral current (FCNC) interactions, which may lead to a sizeable top quark production cross section at HERA [1, 2].

A search for single top quark production is performed using the full $e^\pm p$ data sample collected by the H1 experiment at HERA. The data correspond to an integrated luminosity of 474 pb^{-1} , including 36 pb^{-1} of data taken at $\sqrt{s} = 301$ GeV. The analysis is inspired by and supersedes the previous H1 search for single top quark production based on an integrated luminosity of 118 pb^{-1} [3]. Anomalous single top quark production also has been investigated by the ZEUS collaboration [4] and by the LEP experiments [5].

In the present analysis, single top quark production is detected via the decay of the top quark $t \rightarrow bW$. In the case of leptonic decays of the W boson, $W \rightarrow \ell\nu$, the signature is a charged lepton (electron or muon) and missing transverse momentum, accompanied by a hadronic final state X with a high transverse momentum (P_T) due to the b quark. Events of this topology have been studied in a recently published analysis of events with isolated leptons and missing transverse momentum by H1 [6]. In the case of the hadronic W boson decay channel, $W \rightarrow q\bar{q}$, the signature of single top quark production consists of three high P_T jets with an invariant mass compatible with the top quark mass. A multivariate discriminant based on a neural network is used to differentiate top quark production from SM background. A possible contribution from a top quark signal is extracted using the method of fractional event counting [7].

2 Single Top Quark Production

The dominant process of SM single top quark production at HERA is via charged current (CC) production $ep \rightarrow \nu tbX$. The cross section for this process has been estimated [8] to be $\mathcal{O}(1)$ fb and is thus not observable with the available integrated luminosity. Anomalous single top quark production within FCNC models, where the coupling of a top quark with an up-type quark U via a photon is described by a coupling $\kappa_{tU\gamma}$, is illustrated in figure 1. This process, as well as FCNC top quark interactions involving vector couplings to a Z boson V_{tUZ} , can be described by an effective Lagrangian [9]:

$$\mathcal{L}_{eff}^{FCNC} = \sum_{U=u,c} \frac{ee_U}{2\Lambda} \kappa_{tU\gamma} \bar{t} \sigma_{\mu\nu} A^{\mu\nu} U + \frac{g}{2 \cos \theta_W} V_{tUZ} \bar{t} \gamma_\mu U Z^\mu + \text{h.c.},$$

where $\sigma_{\mu\nu} = (i/2) [\gamma^\mu, \gamma^\nu]$, θ_W is the Weinberg angle, e and g are the couplings to the electromagnetic and weak gauge groups with $U(1)$ and $SU(2)$ symmetries, respectively, e_U is the electric charge of up-type quarks, $A^{\mu\nu}$ is the field strength tensor of the photon, Z^μ is the vector field of the Z boson and Λ is a scale parameter.

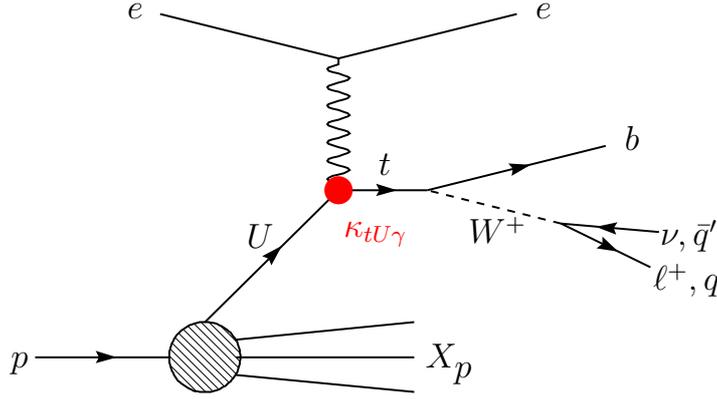

Figure 1: Anomalous single top quark production in ep collisions via a FCNC coupling $\kappa_{tU\gamma}$.

As the top quark mass is comparable to the ep centre of mass energy at HERA, the interacting parton in the proton must be at high Björken- x . Contributions from the charm quark are therefore neglected ($\kappa_{tc\gamma} \equiv V_{tcZ} \equiv 0$) since the c quark density in the proton is low at high Björken- x . Similarly, the production of anti-top quarks is neglected, as this process involves sea anti-quarks in the initial state.

The simulation of an anomalous single top quark signal is done using the event generator ANOTOP [3], which uses the leading order (LO) matrix elements of the complete $e + q \rightarrow e + t \rightarrow e + b + W \rightarrow e + b + f + \bar{f}'$ process as obtained from the CompHEP program [10]. ANOTOP is used to calculate the production cross section and to study decays of top quarks in the H1 detector. Only top quark decays $t \rightarrow bW$ are considered as suggested by the strict limits on other possible top quark decays [11, 12].

The anomalous single top quark production cross section can then be parametrised as:

$$\sigma(ep \rightarrow etX, \sqrt{s}) = c_\gamma \cdot \kappa_{tU\gamma}^2 + c_Z \cdot V_{tUZ}^2 + c_{\gamma Z} \cdot \kappa_{tU\gamma} \cdot V_{tUZ}. \quad (1)$$

The coefficients c_γ and c_Z are determined with ANOTOP at $\sqrt{s} = 319$ GeV. In this analysis m_{top} is set to 175 GeV and by convention the scale parameter Λ is fixed to m_{top} . If $\Lambda \equiv m_{\text{top}}$ is reduced to 170 GeV, the cross section increases by 25%, mainly due to an increased phase space for the production of top quarks. This mass range encompasses the current top quark mass determination of CDF and DØ $m_{\text{top}} = 172.4 \pm 1.2$ GeV [13] and corresponds to a coefficient range from $c_\gamma = 7.53$ pb to 9.41 pb and $c_Z = 0.26$ pb to 0.32 pb. The values for c_γ include next to leading order (NLO) corrections [14], which increase the LO cross section by 17%. Including these NLO corrections results in an uncertainty related to the choice of the renormalisation and factorisation scales of about 5%. Since the contribution of the Z boson is small and no competitive sensitivity is expected, Z -exchange is neglected in this analysis and only the $\kappa_{tU\gamma}$ coupling is considered. The interference term with coefficient $c_{\gamma Z}$ contributes less than 1% of the total cross section and is therefore also neglected.

3 Standard Model Background Processes

The contributions from SM processes to the background in the leptonic decay channels were studied extensively in the analysis of events with isolated leptons and missing transverse momentum [6] and are only briefly described here. The main SM background process is the production of single W bosons. Further SM background processes may mimic the top quark signature through misidentification or mismeasurement. In the hadronic decay channel the SM background prediction is dominated by multi-jet events produced in photoproduction or neutral current (NC) deep-inelastic scattering (DIS).

Production of single W bosons is modelled by the EPVEC generator [15]. NLO QCD corrections are taken into account by reweighting the generated events [16, 17]. CC DIS events are simulated using the DJANGO [18] generator, which includes first order leptonic QED radiative corrections based on HERACLES [19]. The production of two or more jets in DJANGO is accounted for using the colour-dipole model [20]. The RAPGAP [21] event generator, which implements the Born, QCD Compton and Boson Gluon Fusion matrix elements, is used to model NC DIS events. Direct and resolved photoproduction of jets and prompt photon production are simulated using the PYTHIA [22] event generator. The simulation is based on Born level hard scattering matrix elements with radiative QED corrections. In RAPGAP and PYTHIA, jet production from higher order QCD radiation is simulated using leading logarithmic parton showers while hadronisation is modelled with Lund string fragmentation. The leading order MC prediction from NC DIS and photoproduction processes with two or more high transverse momentum jets is scaled by a factor of 1.2, to account for missing higher order QCD contributions in the MC generators [23, 24]. Further small contributions to the SM background originate from lepton pair production, simulated using the GRAPE generator [25], and from photon wide angle bremsstrahlung, simulated in the WABGEN framework [26].

Generated signal and background events are passed through the GEANT [27] based simulation of the H1 detector, which takes into account the running conditions of the different data taking periods, and are reconstructed and analysed using the same program chain as for the data.

4 Experimental Conditions

A detailed description of the H1 experiment can be found in [28]. Only the detector components relevant to the present analysis are briefly described here. The origin of the H1 coordinate system is the nominal ep interaction point, with the direction of the proton beam defining the positive z -axis (forward region). Transverse momentum is measured in the xy -plane. The pseudorapidity η is related to the polar angle θ by $\eta = -\ln \tan(\theta/2)$. Tracking is provided by the central ($20^\circ < \theta < 160^\circ$) and forward ($7^\circ < \theta < 25^\circ$) tracking detectors. They are used to measure charged particle trajectories, to reconstruct the interaction vertex and to complement the measurement of hadronic energies. The tracking detectors are surrounded by a finely segmented Liquid Argon (LAR) calorimeter [29] that covers the polar angle range $4^\circ < \theta < 154^\circ$. Electromagnetic shower energies are measured with a precision of $\sigma(E)/E = 12\%/\sqrt{E/\text{GeV}} \oplus 1\%$ and hadronic energies with $\sigma(E)/E = 50\%/\sqrt{E/\text{GeV}} \oplus 2\%$, as measured in test beams [30, 31]. In the backward region, energy measurements are provided by a

lead/scintillating-fibre (SpaCal) calorimeter¹ [32] covering the range $155^\circ < \theta < 178^\circ$. The LAr calorimeter and inner tracking detectors are enclosed in a super-conducting magnetic coil with a field strength of 1.16 T. From the curvature of charged particle trajectories in the magnetic field, the central tracking system provides transverse momentum measurements with a resolution of $\sigma_{P_T}/P_T = 0.005P_T/\text{GeV} \oplus 0.015$ [33]. The return yoke of the magnetic coil is the outermost part of the detector and is equipped with streamer tubes forming the central muon detector ($4^\circ < \theta < 171^\circ$). In the forward region of the detector ($3^\circ < \theta < 17^\circ$) a set of drift chambers detects muons and measures their momenta using an iron toroidal magnet. The luminosity is determined from the rate of the Bethe-Heitler process $ep \rightarrow ep\gamma$, measured in a photon detector located close to the beam pipe at $z = -103$ m, in the backward direction.

The LAr calorimeter provides the main trigger for events in this analysis. The trigger efficiency is almost 100% for events with an electron with an energy above 10 GeV. Events with muons are triggered by an imbalance in transverse momentum measured in the calorimeter P_T^{calo} . The trigger efficiency is $\sim 60\%$ for $P_T^{\text{calo}} = 12$ GeV, rising to $\simeq 98\%$ for $P_T^{\text{calo}} > 25$ GeV. Events with jets have a trigger efficiency of nearly 100% for events with $P_T^{\text{jet}} > 25$ GeV [34].

In order to remove background events induced by cosmic rays and other non- ep sources, the event vertex is required to be reconstructed within ± 35 cm in z of the average interaction point. In addition, topological filters and timing vetoes are applied.

5 Data Analysis

5.1 Particle Identification and Event Reconstruction

Particle identification and hadronic final state reconstruction are described in detail in [6] and are only briefly summarised here. Electrons and photons are characterised [35] by compact and isolated electromagnetic clusters in the LAr calorimeter or SpaCal. Muon identification is based on a track in the inner tracking systems associated with signals in the muon detectors [36, 37]. Calorimeter energy deposits and tracks not previously identified as electron, photon or muon candidates are used to form combined cluster-track objects, from which the hadronic final state is reconstructed [34, 38]. Jets are reconstructed from these combined cluster-track objects using an inclusive k_T algorithm [39, 40] with a minimum transverse momentum of 4 GeV. The missing transverse momentum P_T^{miss} in the event is derived from all detected particles and energy deposits in the event.

Strict isolation criteria are applied to electron and muon candidates. For electrons a track with a distance of closest approach (DCA) to the cluster of less than 12 cm is required to reject photons. The calorimetric energy measured within a distance in the pseudorapidity-azimuth ($\eta - \phi$) plane $D = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.5$ around the electron cluster is required to be below 3% of its energy. Furthermore, electrons are required to be isolated from jets by a distance $D(e; \text{jet}) > 1.0$ to any jet axis, and in the region $\theta > 45^\circ$ by a distance $D(e; \text{track}) > 0.5$ from any track. A muon candidate may have no more than 5 GeV energy deposited in a cylinder, centred on the muon track direction, of radius 25 cm and 50 cm in the electromagnetic and hadronic sections of the LAr calorimeter, respectively. Muon candidates are required to be separated from any jet by a distance $D(\mu; \text{jet}) > 1.0$ and from any track by $D(\mu; \text{track}) > 0.5$.

¹This device was installed in 1995, replacing a lead-scintillator “sandwich” calorimeter [28].

5.2 Systematic Uncertainties

The following experimental systematic uncertainties are considered:

- The uncertainty on the electromagnetic energy scale varies depending on the polar angle from 0.7% to 2%. The polar angle measurement uncertainty is 3 mrad for electromagnetic clusters.
- The scale uncertainty on the transverse momentum of high P_T muons is 2.5%. The uncertainty on the muon polar angle measurement is 3 mrad.
- The hadronic energy scale is known within 1.5% [41]. The uncertainty on the jet polar angle measurement is 10 mrad [34].
- The uncertainty on the trigger efficiency is 3%.
- The luminosity measurement has an uncertainty of 3%.

The effect of the above systematic uncertainties on the MC expectation is determined by varying the experimental quantities by ± 1 standard deviation in the MC samples and propagating these variations through the whole analysis.

Additional model uncertainties are attributed to the SM MC generators described in section 3. A theoretical uncertainty of 15% is used for the predicted contributions from EPVEC [16]. In the electron and muon channels the CC background contribution, which is modelled using DJANGO, is attributed a systematic error of 50% [6]. The contributions from background processes modelled using RAPGAP, PYTHIA, GRAPE and WABGEN are attributed 30% model uncertainties [6]. In the hadronic channel, the background processes with multi-jet final states modelled using RAPGAP and PYTHIA are attributed a 10% model uncertainty determined from the comparison to data in an extended phase space.

5.3 Electron and Muon Channels

The search for single top quark production in the electron and muon channels is based on the selection described in [6]. Isolated electrons and muons with a transverse momentum $P_T^\ell > 10$ GeV in the polar angle range $5^\circ < \theta_\ell < 140^\circ$ are selected in events with a missing transverse momentum $P_T^{\text{miss}} > 12$ GeV. In the electron channel, 39 events are found, compared to a SM prediction of 43.1 ± 6.0 . In the muon channel, 14 events are observed, compared to a SM prediction of 11.0 ± 1.8 . To estimate a potential top contribution to this sample, a top quark candidate is reconstructed from its decay products (lepton ℓ , neutrino ν and b quark), and the compatibility with single top quark production via FCNC is tested using a multivariate discriminant method.

The neutrino four-vector P_ν is reconstructed using the transverse and longitudinal momentum balance of the event. The transverse momentum of the neutrino is reconstructed by assuming:

$$\vec{P}_T^\nu \equiv \vec{P}_T^{\text{miss}}.$$

If the scattered electron is detected in addition to the isolated lepton, the four-vector of the neutrino can be fully reconstructed by exploiting the energy and longitudinal momentum balance:

$$\sum_i (E^i - P_z^i) + (E^\nu - P_z^\nu) = 2E_e^0 = 55.2 \text{ GeV}, \quad (2)$$

where the sum runs over all detected particles, P_z is the momentum along the proton beam axis and E_e^0 is the electron beam energy. For events with more than one isolated electron, the electron with the lower transverse momentum is assumed to be the scattered electron [42]. If the scattered electron is not detected, the constraint $M^{\ell\nu} \simeq M_W = 80.42 \text{ GeV}$ is applied. In the case that two physical solutions are obtained for $(E^\nu - P_z^\nu)$, the more probable solution according to the ANOTOP simulation is chosen [42]. A small fraction of events is removed in the case when the reconstruction algorithm finds no physical solution. In the electron channel, 38 events are selected after this neutrino reconstruction, while 39.7 ± 5.6 are expected from the SM. In the muon channel, 13 events are selected, while 10.7 ± 1.6 are expected from the SM. The selection efficiency for generated ANOTOP events at this stage is 49% (44%) for the electron (muon) channel. The four-vector of the b -jet candidate is defined as the four-vector of the hadronic final state. The four-vector of the top quark candidate is reconstructed as the sum of the four-vectors of the isolated lepton, the neutrino and the b -jet candidate. This includes top quark decays where the W boson decays via $W \rightarrow \tau \rightarrow e(\mu)$. Figure 2 shows the reconstructed top mass in the combined electron and muon channels. The data are in overall agreement with the SM prediction, while a slight excess of data events is observed in the top quark mass range.

In addition to the kinematic reconstruction of the top quark decay the lepton charge is also exploited, as the decay chain $t \rightarrow bW^+ \rightarrow \ell\nu b$ produces only positively charged leptons. Well measured negatively charged leptons are rejected by requiring $q_\ell \cdot \frac{|\kappa|}{\delta\kappa} > -1.0$ where q_ℓ is the charge of the lepton, $|\kappa|$ is the curvature of the track associated to the lepton and $\delta\kappa$ is the error on the curvature. This requirement is only applied in the central region where the charge determination by the tracking detectors is reliable. Table 1 summarises the event yield in the electron and muon channels for the resulting top preselection. In the electron channel 30 events are selected, while 31.5 ± 4.0 are expected from the SM. In the muon channel, eight events are selected, while 8.0 ± 0.9 are expected from the SM.

The following observables are then used to further discriminate single top quark production via FCNC against SM background:

- P_T^b , the transverse momentum of the b -jet candidate;
- $M^{\ell\nu b}$, the invariant mass of the reconstructed top quark;
- $\theta_{W^*}^\ell$, the W decay angle calculated as the angle between the lepton momentum in the W rest frame and the W direction in the top quark rest frame.

Distributions of these observables are shown in figures 3 (a-c) and 4 (a-c) for the electron and muon channels, respectively. Good overall agreement of the data with the SM expectation is seen in all distributions. For the discrimination of top and background events, a multivariate discriminator based on a multilayer perceptron (MLP) neural network was trained on the signal and background simulations. Figures 3 (d) and 4 (d) show the MLP discriminator output

distributions for the electron and muon channels, respectively. A good agreement is observed between data and SM expectation, with some events visible in the signal region.

Results from the multivariate analysis are cross checked with a cut-based top selection requiring for the top preselected events in addition $P_T^b > 30$ GeV and $M^{\ell\nu b} > 140$ GeV. The resulting event yields are also shown in table 1. In this selection five events are selected in the electron channel, while 3.2 ± 0.4 are expected from the SM. In the muon channel, four events are selected, while 2.1 ± 0.3 are expected from the SM. This sample includes all five top-like events found in the previous analysis [3]. If the charge requirement is not applied, the corresponding event yields are seven selected events for an expectation of 4.1 ± 0.7 in the electron channel, and six events for 2.8 ± 0.4 expected in the muon channel.

5.4 Hadronic Channel

The hadronic decay of the W boson from the top decay $t \rightarrow bW \rightarrow bq\bar{q}'$ leads to events with at least three jets with high transverse momenta. SM background arises mainly from multi-jet events in photoproduction or NC DIS. A top preselection is defined by selecting events with at least three jets in the pseudorapidity range $-0.5 < \eta^{\text{jet}} < 2.5$. The jets are ordered by the magnitude of their transverse momenta and only events with $P_T^{\text{jet}1} > 40$ GeV, $P_T^{\text{jet}2} > 30$ GeV and $P_T^{\text{jet}3} > 15$ GeV are selected. A cut on the scalar sum of the jet transverse momenta $\sum P_T^{\text{jet}} > 110$ GeV is also applied. In addition, one of the jet pairings must yield an invariant mass between 65 GeV and 95 GeV, corresponding to a window around the nominal W mass with a width of twice the mass resolution obtained for hadronic W decays [42]. The remaining jet that is not used to form the W candidate is considered to originate from the b quark and is required to have a minimum $P_T > 25$ GeV. The yield for this top preselection is given in table 1. A total of 404 events are selected, compared to a SM prediction of 388 ± 32 events. The selection efficiency for generated ANOTOP events is 42% at this stage. Analogously to the leptonic channel observables for the discrimination of the top quark signal from the QCD background are chosen:

- P_T^b , the transverse momentum of the b -jet candidate;
- M^{jets} , the invariant mass of all jets in the event corresponding to the mass of the top quark for signal events;
- $\theta_{W^*}^q$, the W decay angle defined as the angle in the W rest frame between the lowest P_T jet of the two jets associated to the W decay and the W direction in the top quark rest frame.

Distributions of these three observables are shown in figure 5 (a-c), compared to the SM expectation and the simulated top signal. Good agreement between the data and the SM simulation is seen for all three distributions. For the discrimination of top and background events, an MLP discriminator was trained on the signal and background simulations. Figure 5 (d) shows the discriminator output distribution for the signal and background simulations. Also shown are the data events as classified by the discriminator and a good agreement is observed between data

and SM expectation. This distribution is used to extract a possible signal, as described in the next section.

A cut-based top selection is also performed in the hadronic channel. The transverse momentum of the b -jet candidate has to fulfill $P_T^b > 40$ GeV and the reconstructed top quark mass $150 < M^{\text{jets}} < 210$ GeV. The number of candidate events selected is 128, compared with 123 ± 13 events expected from SM processes.

6 Results

The discriminant distributions observed in all three channels are in correspondence with the SM expectation as shown in figures 3 (d), 4 (d) and 5 (d). Since no significant indication for the production of single top quarks is observed, upper limits on the cross section are derived using the method of fractional event counting which takes efficiencies, statistical and systematic uncertainties into account [7]. This method is cross-checked using a modified frequentist approach [43] which is found to yield similar results. Also expected cross section limits are determined by assuming that a top quark signal is a fluctuation of Poisson distributed SM background. An ensemble of toy experiments with this hypothesis is conducted using the background prediction and calculating a cross section limit at 95% CL for each toy experiment. The mean of the resulting distribution is reported as the expected cross section limit at 95% CL.

For all channels combined an upper bound on the cross section for single top quark production via FCNC is obtained at the 95% CL:

$$\sigma(ep \rightarrow etX, \sqrt{s} = 319 \text{ GeV}) < 0.25 \text{ pb.}$$

This cross section limit is reported for $\sqrt{s} = 319$ GeV, taking into account the ratio 0.70 of the predicted signal cross sections at $\sqrt{s} = 301$ GeV and 319 GeV [14]. Table 2 lists the observed and expected cross section limits for the individual channels, the combined leptonic channels, and all channels combined.

The top-like events observed in the data at high values of the discriminant lead to observed limits that are weaker than the expected limits. This difference corresponds to the slightly higher observed event yields from the cut-based top selection compared to the predictions. Extracting a production cross section from the discriminant distributions gives for all channels combined $\sigma(ep \rightarrow etX, \sqrt{s} = 319 \text{ GeV}) = 0.11 \pm 0.07 \text{ pb}$. This value is compatible with zero within two standard deviations.

The limits on the cross section are converted to limits at 95% CL on the anomalous FCNC coupling $\kappa_{t\bar{u}\gamma}$ using equation 1. This results in an upper limit on $\kappa_{t\bar{u}\gamma} < 0.16 - 0.18$ for the parameter range $\Lambda \equiv m_{\text{top}} \equiv 170 - 175$ GeV, respectively. Figure 6 shows current limits from experiments in the $\kappa_{t\bar{u}\gamma} - V_{t\bar{u}Z}$ plane. The limits on branching fractions of anomalous decays of top quarks obtained by the CDF experiment at Tevatron [11, 12] are converted to limits on couplings using the conventions described in section 2. The limit on the branching fraction $\mathcal{B}(t \rightarrow qZ) < 3.7\%$ at 95% CL reported by CDF [11] corresponds to the strictest limit on the $V_{t\bar{u}Z}$ coupling. For ease of comparison, the H1 limit on the coupling $\kappa_{t\bar{u}\gamma}$ is also converted to a limit on the branching fraction $\mathcal{B}(t \rightarrow u\gamma) < 0.64\%$, also shown in table 2. The

LEP experiments have also searched for anomalous single top quark production [5]. The limit obtained by the ZEUS experiment [4] using 130 pb^{-1} of data is similar to the H1 bound based on the full HERA data, mainly reflecting the slight excess of top-like events observed by H1, but not by ZEUS. The present analysis explores a domain not covered by other colliders.

7 Summary

A search for single top quark production via FCNC at HERA is performed using the full $e^\pm p$ data sample, corresponding to an integrated luminosity of 474 pb^{-1} . The search is based on a sample of events with isolated leptons and missing transverse momentum and a sample of multi-jet events. No evidence for single top quark production is observed. Within FCNC models the top quark production cross section is extracted from multivariate discriminator distributions using the method of fractional event counting. An upper limit at 95% CL on the production cross section:

$$\sigma(ep \rightarrow etX, \sqrt{s} = 319 \text{ GeV}) < 0.25 \text{ pb}$$

is established. This result is translated into a limit on the anomalous coupling $\kappa_{tu\gamma}$ at 95% CL:

$$\kappa_{tu\gamma} < 0.18$$

if the scale of the new physics $\Lambda \equiv m_{\text{top}} \equiv 175 \text{ GeV}$. This corresponds to a limit on the branching ratio $\mathcal{B}(t \rightarrow u\gamma) < 0.64\%$.

Acknowledgements

We are grateful to the HERA machine group whose outstanding efforts have made this experiment possible. We thank the engineers and technicians for their work in constructing and maintaining the H1 detector, our funding agencies for financial support, the DESY technical staff for continual assistance and the DESY directorate for support and for the hospitality which they extend to the non-DESY members of the collaboration.

H1 Search for Single Top Production at HERA ($e^\pm p, 474 \text{ pb}^{-1}$)				
Electron Channel		Data	Standard Model	Top Efficiency
Top Preselection	Isolated Leptons	39	43.1 ± 6.0	49%
	ν Reconstruction	38	39.7 ± 5.6	49%
	Cut on Lepton Charge	30	31.5 ± 4.0	49%
	Cut-based Top Selection	5	3.2 ± 0.4	40%
Muon Channel		Data	Standard Model	Top Efficiency
Top Preselection	Isolated Leptons	14	11.0 ± 1.8	44%
	ν Reconstruction	13	10.7 ± 1.6	44%
	Cut on Lepton Charge	8	8.0 ± 0.9	44%
	Cut-based Top Selection	4	2.1 ± 0.3	36%
Hadron Channel		Data	Standard Model	Top Efficiency
Top Preselection		404	388 ± 32	42%
Cut-based Top Selection		128	123 ± 13	33%

Table 1: Observed and predicted numbers of events in the electron, muon and hadronic channels for the steps of the top preselection and in the cut-based top selection. The top signal efficiency is estimated using ANOTOP. The quoted errors take into account all statistical and systematic uncertainties.

H1 Search for Single Top Production ($e^\pm p$, 474 pb^{-1})				
Channel	Upper Limit at 95% CL			
	$\sigma(ep \rightarrow tX, \sqrt{s} = 319 \text{ GeV})$		$\kappa_{tu\gamma}$	$\mathcal{B}(t \rightarrow u\gamma)$
	Observed [pb]	Expected [pb]		
Electron	0.40	0.24	0.21 – 0.23	0.82 – 1.02
Muon	0.30	0.22	0.18 – 0.20	0.61 – 0.76
Electron+Muon	0.27	0.15	0.17 – 0.19	0.55 – 0.69
Hadronic	0.42	0.27	0.21 – 0.24	0.86 – 1.07
Combined	0.25	0.12	0.16 – 0.18	0.51 – 0.64

Table 2: Observed and expected upper limits at 95% CL on the single top production cross section at $\sqrt{s} = 319 \text{ GeV}$ in the electron, muon, hadronic and combined channels. Also shown are upper limits on the anomalous coupling $\kappa_{tu\gamma}$ and on the branching fraction $\mathcal{B}(t \rightarrow u\gamma)$. These limits are shown for $\Lambda \equiv m_{\text{top}} \equiv 170 - 175 \text{ GeV}$.

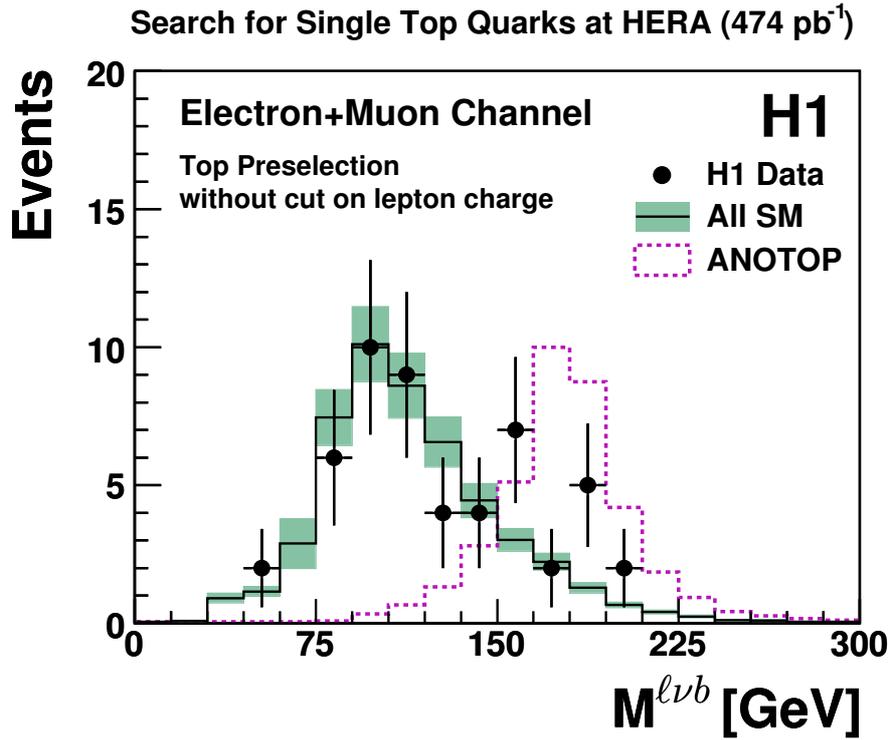

Figure 2: Distribution of the reconstructed top mass $M^{\ell\nu b}$ in the electron and muon channels after ν reconstruction but before the cut on the lepton charge. The data are shown as points, the total SM expectation as the open histogram with systematic and statistical uncertainties added in quadrature (shaded band). Also shown is the ANOTOP prediction with arbitrary normalisation (dashed histogram).

Search for Single Top Quark Production at HERA (474 pb⁻¹)

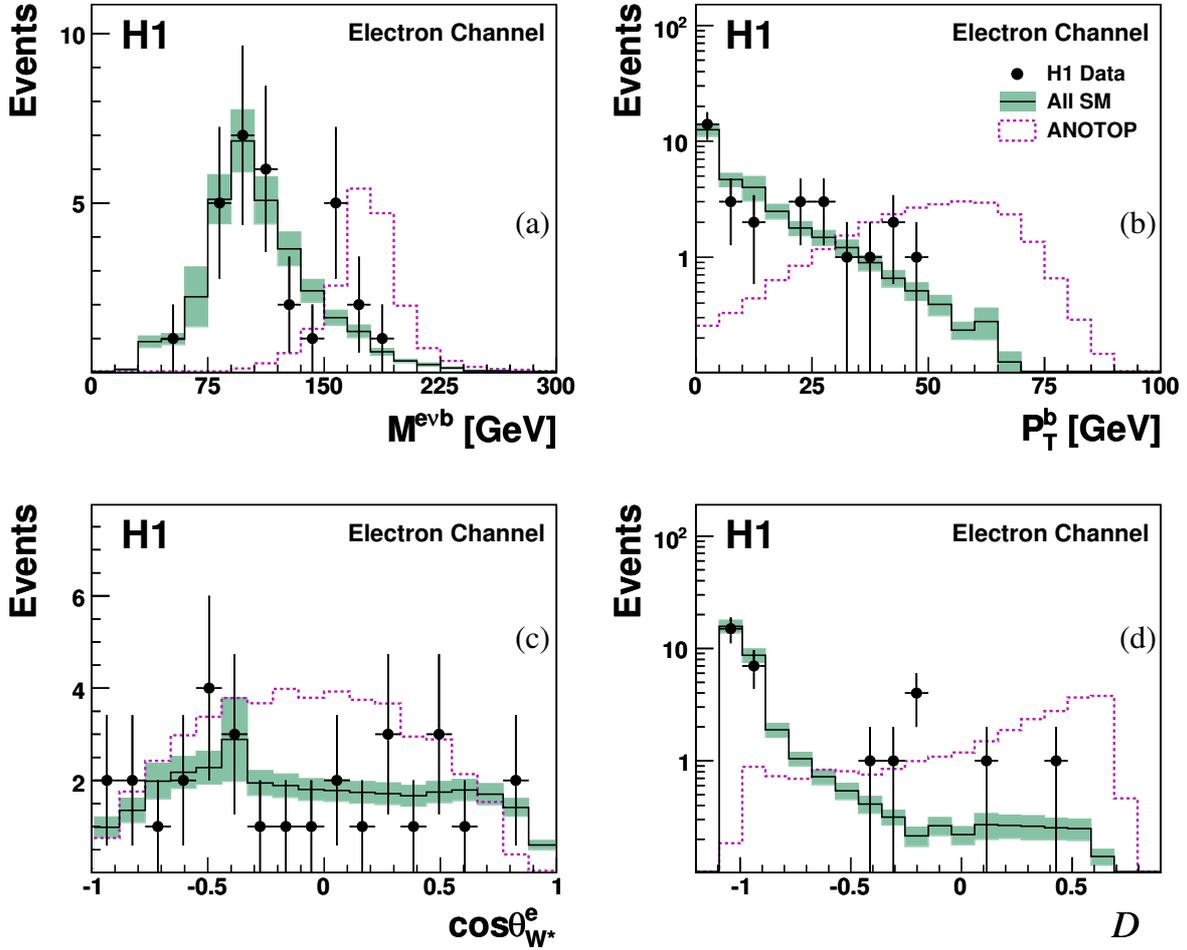

Figure 3: Distributions of observables in the electron channel used to differentiate single top production from SM background processes in the top preselection. Shown are the reconstructed top mass M^{evb} (a), the transverse momentum of the reconstructed b -jet candidate P_T^b (b), the W decay angle $\cos\theta_{W*}^e$ (c), and the combination of these observables into a MLP-based discriminant D (d). The data are shown as points, the total SM expectation as the open histogram with systematic and statistical uncertainties added in quadrature (shaded band). Also shown is the signal prediction with arbitrary normalisation (dashed histogram).

Search for Single Top Quark Production at HERA (474 pb⁻¹)

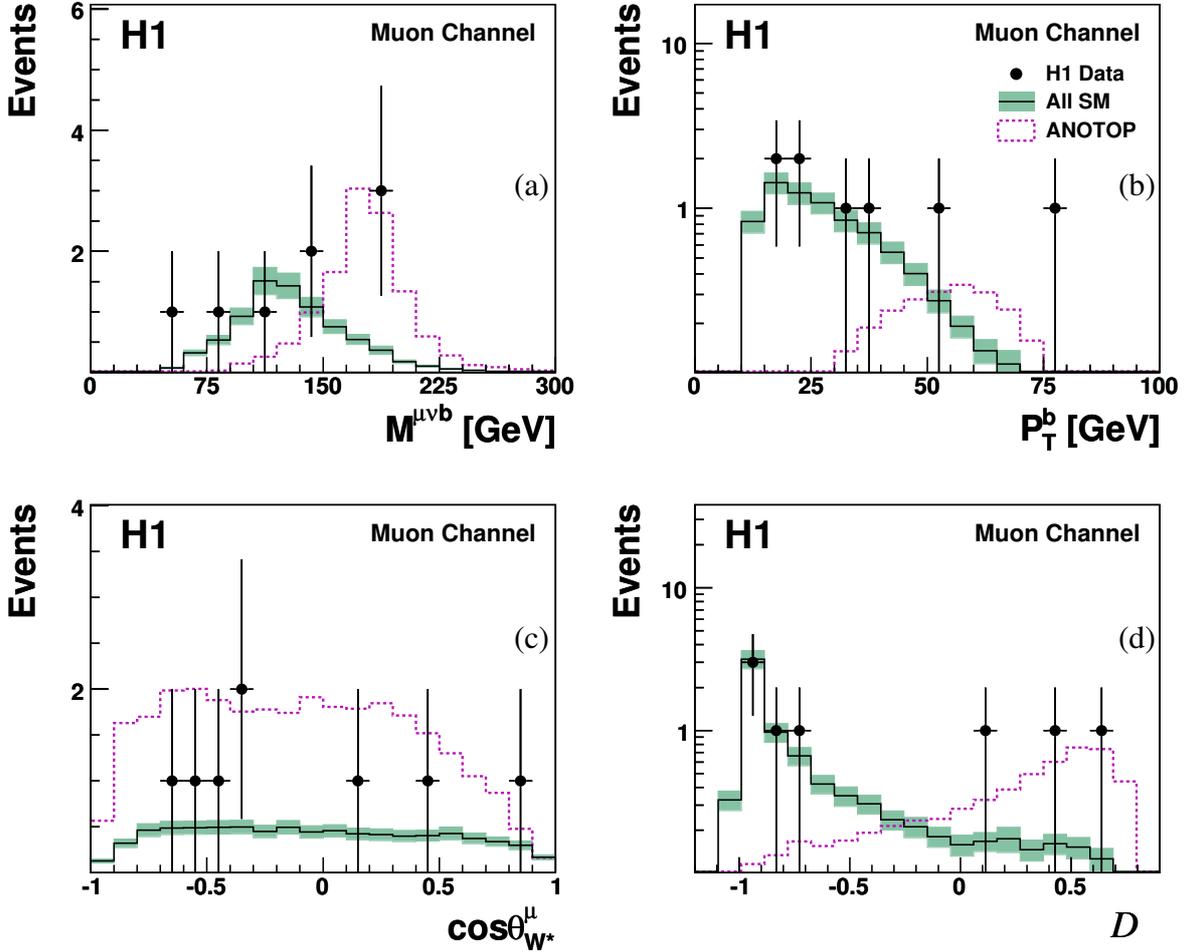

Figure 4: Distributions of observables in the muon channel used to differentiate single top production from SM background processes in the top preselection. Shown are the reconstructed top mass $M^{\mu\nu b}$ (a), the transverse momentum of the reconstructed b -jet candidate P_T^b (b), the W decay angle $\cos\theta_{W^*}^\mu$ (c), and the combination of these observables into a MLP-based discriminant D (d). The data are shown as points, the total SM expectation as the open histogram with systematic and statistical uncertainties added in quadrature (shaded band). Also shown is the signal prediction with arbitrary normalisation (dashed histogram).

Search for Single Top Quark Production at HERA (474 pb⁻¹)

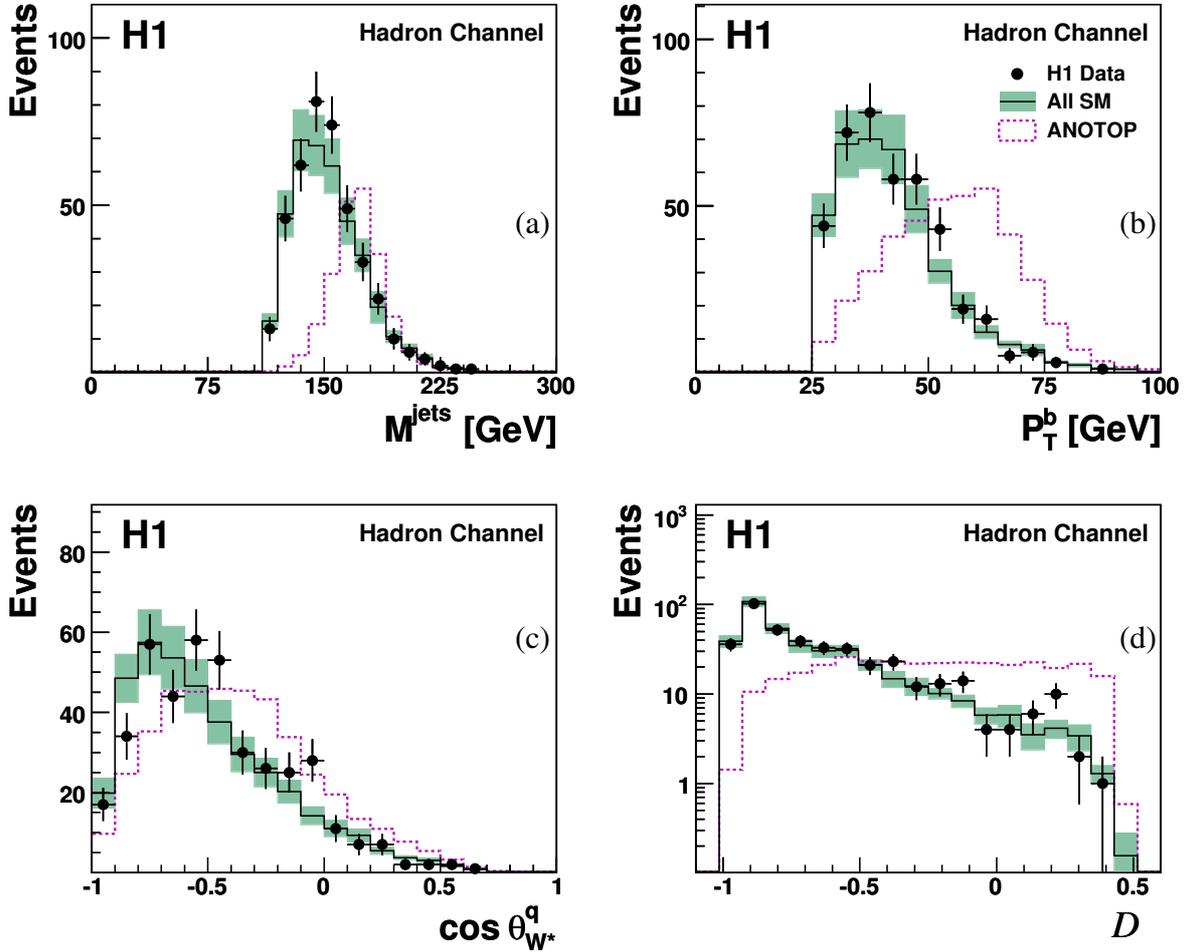

Figure 5: Distributions of observables in the hadronic channel used to differentiate single top production from SM background processes in the top preselection. Shown are the invariant mass of all jets M^{jets} (a), the transverse momentum of the b -jet candidate P_T^b (b), the W decay angle $\cos \theta_{W^*}^q$ (c), and the combination of these observables into a MLP-based discriminant D (d). The data are shown as points, the total SM expectation as the open histogram with systematic and statistical uncertainties added in quadrature (shaded band). Also shown is the signal prediction with arbitrary normalisation (dashed histogram).

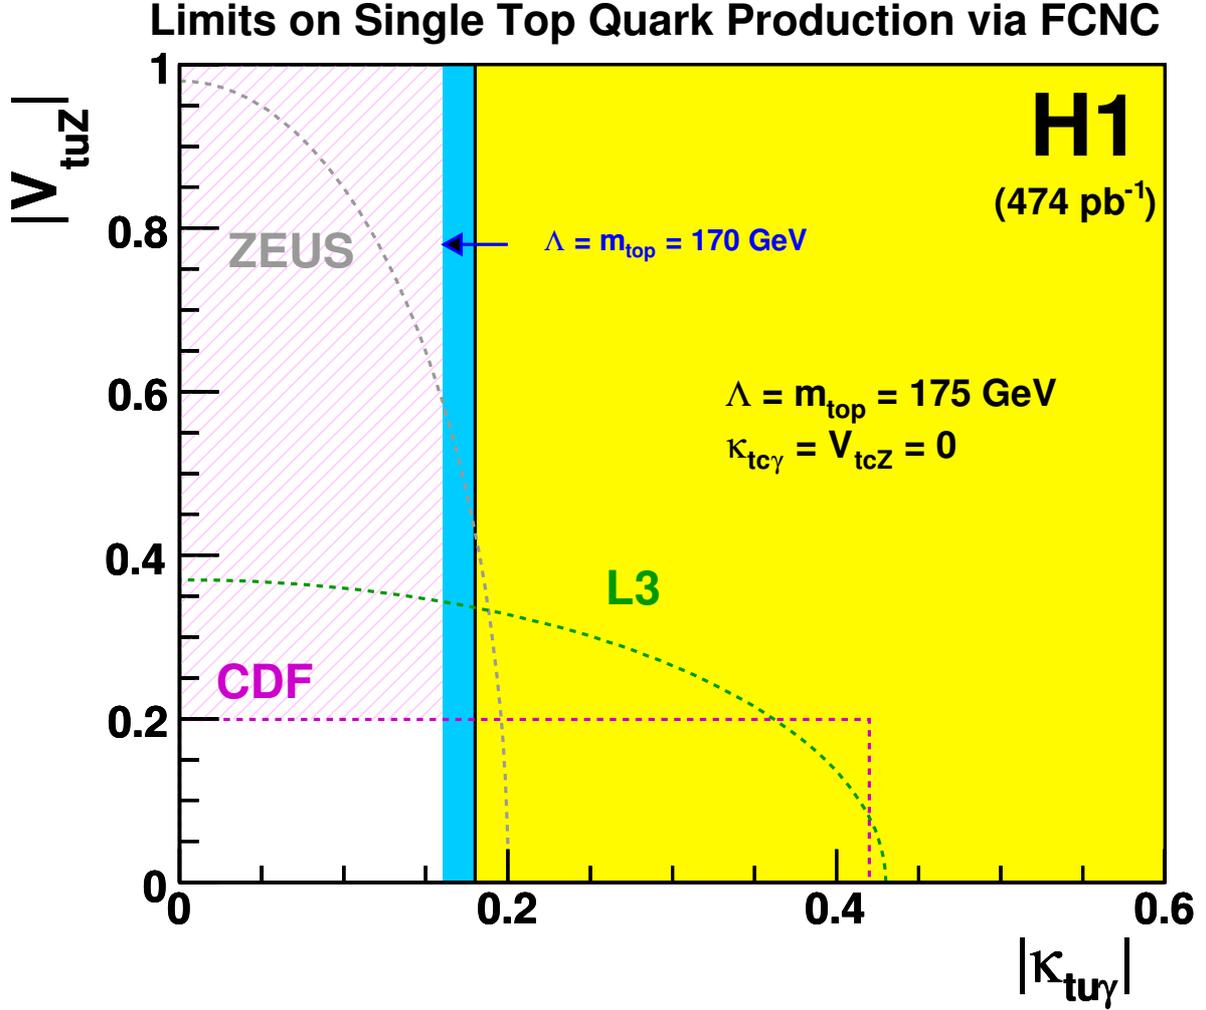

Figure 6: Upper limits at 95% CL on the anomalous $\kappa_{tu\gamma}$ and V_{tuZ} couplings obtained assuming $\Lambda \equiv m_{top} \equiv 175 \text{ GeV}$. Anomalous couplings of the charm quark are neglected: $\kappa_{tc\gamma} = V_{tcZ} = 0$. The domain excluded by H1 is represented by the light shaded area. The dark shaded band shows the region additionally excluded if $\Lambda \equiv m_{top}$ is varied to 170 GeV. The hatched area corresponds to the domain excluded at the Tevatron by the CDF experiment [11, 12]. Also shown are limits obtained at LEP by the L3 experiment [5] and at HERA by the ZEUS experiment [4].
